Manager at Everris.

“These days anthracnose is an altogether different proposition and can cause significant damage if left unchecked. It seems that the increased pressure of ever more intensive management, coupled with greater demands for play and combined with ever more extremes of weather are creating conditions for the disease to flourish and strike harder and harder.”

New order management

A new disease dimension calls for a new order of disease management with a more integrated consideration of the causes and the control of anthracnose. More emphasis is given to summer stress facilitating easier and quicker leaf infection and disease development, and environmental conditions that push a sedentary saprophytic thatch residing fungus into full parasitic mode.

Rising temperatures over compacted turf with dry patch symptoms is a ‘flag up’ for anthracnose. Moisture from summer showers or irrigation with nowhere to go except into the thatch will create and maintain surface wetness and high humidity, the ideal conditions for pathogen activity and anthracnose disease.

Wetting agents to improve soil permeability and water holding capacity, to avoid dry patch and maintain stress-free turf in summer, clearly have an important part to play in anthracnose management. Discussing the advantages of their Tricure range of wetting agents in last month’s Greenkeeper International, Headland Amenity specifically cited the need “to get water into the root zone and keep it there to reduce the stress associated with turf diseases such as anthracnose.”

Dry compacted soil also impacts on fertility because applied nutrients can only enter the root zone and be accessed by roots when in solution. Other fertility concerns related to anthracnose revolve around contemporary trends in overall fertiliser use.

Abrasive aspects of anthracnose

Aeration and scarification employed to avoid and alleviate stress can actually aggravate anthracnose especially when used during high risk periods. Anthracnose is also aggravated by traditional summer practices such as low cutting heights and frequent application of top dressings to reduce stress, as well as occasional rolling for tournaments.

The key and common factor is damage to grass leaves and stems however subtle that may be. I’m reminded of a comment made by David Senior at Vitax describing anthracnose “as tiny discrete yellow patches of infection corresponding to pitch marks left by golf balls and causing sufficient abrasion for fungal entry.”

The abrasive effect of tiny silica (sand) particles in top dressings on grass plant surfaces is sufficient to open up grass foliage for anthracnose infection, especially if the dressings are well worked in.

Measures to alleviate stress should be carried out when anthracnose risk is low says Dr Watson, adding how greenkeepers can consult Syngenta’s Greencast Website where anthracnose risk is plotted throughout the season on easy to read graphs.

Greenkeepers can use risk forecasts to time proactive fungicide applications more effectively to get the best results, and for tailoring fertiliser applications and synchronising other turf management as low cutting heights and frequent application of top dressings to reduce stress, as well as occasional rolling for tournaments.

Changing face of fungicides

Gone are the days when anthracnose was a side issue in autumn turf management and dispatched by fungicide sprays targeted at Fusarium Patch. Anthracnose is now a disease its own right requiring specifically targeted summer sprays when Fusarium is unlikely to be on the greenkeeper’s radar.

Contemporary anthracnose is more difficult to manage but the parallel changing face of fungicides has gone a long way to keep the odds in the greenkeeper’s favour.

“Having pioneered the fungicide radar. Contemporary anthracnose is more difficult to manage but the parallel changing face of fungicides has gone a long way to keep the odds in the greenkeeper’s favour.”

Continuity of disease

“Anthracnose clearly appears in two distinct forms at different times of the year. That said both phases are caused by the same fungus living on thatch in saprophytic or weak parasitic mode. Under combined conditions of high surface wetness/relative humidity and low host ‘resistance’, the anthracnose fungus moves through the grass into full parasitic mode. Inadequate management of either form of anthracnose, foliar blight or basal rot, will leave than much more inoculum to act as a springboard for the following period of high disease pressure and risk.”

Do you want the latest innovation in turf fungicide

Changing face of fungicides

Gone are the days when anthracnose was a side issue in autumn turf management and dispatched by fungicide sprays targeted at Fusarium Patch. Anthracnose is now a disease its own right requiring specifically targeted summer sprays when Fusarium is unlikely to be on the greenkeeper’s radar.

Contemporary anthracnose is more difficult to manage but the parallel changing face of fungicides has gone a long way to keep the odds in the greenkeeper’s favour. Twenty years ago it was unusual to find anthracnose on the fungicide label whereas today it is unusual not to.

Prevention is better than cure. “As it is not possible to treat the advanced stages of anthracnose disease, it remains important to treat at the earliest opportunity,” says Joe Kinder.

Dr Watson reminds greenkeepers to remain alert for conditions conducive to the disease, such as high wear areas dominated by annual meadow grass and where outbreaks have been experienced in the past.

Nutrition is recognised as having a central role in grass resilience to anthracnose with tank mixing of fungicides and nutrients increasingly at the forefront of current thinking.

“It is important we take an integrated approach and focus on preparing surfaces without stressing the turf,” says Henry Bechelet, “and making sure we get the nutritional inputs right. We also need to use properly targeted fungicides to prevent significant damage taking hold.”

Sherriff Amenity is closely focused on tank mixing strategies. “Having pioneered the fungicide and nutrient tank mixing concept, under an extensive trials programme at STRI, we are able to recommend both traditional and novel management options for anthracnose and other commonly occurring turf diseases”, says Joe.

There is considerably more emphasis, in the fungicide market for anthracnose management than a few decades ago, in appropriate products, more two-and-three-way mixes of different actives and versatile in potency, activity and mode of action.

Rigby Taylor has a six-product fungicide portfolio for anthracnose management.

“We offer a broad spectrum of control options for anthracnose made even more versatile through opportunities to tank mix our products. By adjusting rates greenkeepers can obtain a wide range of fungicide chemistry in a single spray without exceeding the maximum dose rate for an individual product as stipulated on the label,” concludes Peter Corbett.

Continuity of disease

Anthracnose clearly appears in two distinct forms at different times of the year. That said both phases are caused by the same fungus living on thatch in saprophytic or weak parasitic mode. Under combined conditions of high surface wetness/relative humidity and low host ‘resistance’, the anthracnose fungus moves through the grass into full parasitic mode. Inadequate management of either form of anthracnose, foliar or basal rot, will leave much more inoculum to act as a springboard for the following period of high disease pressure and risk.

The late autumn form of anthracnose occurring in November has overtaken the late summer form of anthracnose historically occurring in autumn.
“I’m based in Cornwall but it’s well worth the trip every January whether I drive or take a flight. There is something for every greenkeeper at every level”
Mike Bush MG, Course Manager, St Mellion International Golf Club

better the devil you know

Henry Bechelet, Technical Sales Manager at Everris, turns detective to investigate Fusarium and how to deal with it.

Know your enemy

If we want to minimise the occurrence of damaging disease attacks, it is essential to know the pathogens and understand what it is trying to do.

The Microdochium patch pathogens, Microdochium nivale's single aim in life is to complete its life cycle and reproduce. The problem we have, as turf managers, is that it does this at the expense of the grass plant. The turf, in effect, is the collateral damage.

Stages of life cycle

Laying in wait

When inactive, Microdochium nivale survives in the thatch or soil as microscopic spores or dormant mycelium. The spores can remain viable for up to two years and withstand extremely low temperatures (-20°C). They lie in wait for favourable conditions to develop.

Germination

The spores begin to germinate in cool wet conditions. This can happen at temperatures between 15°C and -6°C with the ideal range being 0-6°C (combined with periods of leaf wetness for more than ten hours a day).

When the spores germinate they produce long, branching hyphae, tubular structures that search for nutrients to fuel further growth and development.

Penetration / Infection

Specialist hyphae infect the plant by penetrating outer cell walls of leaf sheaths and leaf blades near the soil. Infection can also proceed through the stomata in the leaves and progress rapidly through the plant.

Mycelial growth

Nutrient absorbing hyphae draw resources from the plant, which is transported from the host to the fungus to allow it to develop and produce further mycelial networks.

This stage can occur extremely quickly with complete colonisation of the leaf possible in the space of 72 hours. This is when the real damage starts. At this stage, the mycelium growth enables the patches to spread outwards.

Fusarium finally produces fruiting bodies containing spores that are released to disperse in wind and water, continuing the cycle of disease. The pathogen population will boom exponentially if cool, damp conditions persist.

It cannot be emphasised enough that the Microdochium nivale pathogen is a merciless parasite. It is solely concerned with its own reproduction, which is achieved by taking resources from its host grass plant. It has no care for the health of the turf and will draw all life from it because the next generation of spores are sent away to find a different host to prey upon.

Test your knowledge

1. What are the conditions that favour the germination of the Microdochium Patch spores?
2. How does the pathogen fuel its growth and development?
3. What are the main symptoms of Microdochium Patch disease?
4. Why is it best practice to rotate active ingredients or use products with multiple active ingredients?
5. When in the pathogen lifecycle is it best to apply the active ingredient fludioxonil?
If we want to minimise the occurrence of damaging disease attacks, it is essential to know the pathogen and understand what it is trying to do.

2. How does the pathogen fuel its growth and development?
3. What are the main symptoms of Microdochium Patch disease?
4. Why is it best practice to rotate active ingredients or use products with multiple active ingredients?
5. When in the pathogen lifecycle is it best to apply the active ingredient fludioxonil?
The symptoms
Initial symptoms begin to show as small brown patches emerging in localised areas. The symptoms are a result of the pathogen causing leaf death due to extensive infection and nutrient withdrawal. Mycelium may also be visible at the edges of the patches as the fungi spreads. As the patches enlarge, the centre becomes water-soaked and paler as a result of the deteriorating leaf structure collapsing and beginning to degrade. These symptoms begin to show quite late in the life-cycle of the disease, so early treatment and a preventative approach is essential to limit the potential for extensive damage.

Your disease prevention strategy
Prevention is always better than cure, so it is important to create conditions that will limit the development of the disease. An integrated turf management approach uses all the tools in our armoury to achieve this. Maintaining turf health and reducing the risk of disease attack begins with sound cultural practices, such as:
- Creating a freely draining turf system with soil profile management, thatch reduction and drainage systems
- Keeping the turf leaf as dry as possible by brushing and switching, dew dispersants, managing irrigation inputs, reducing shade and improving airflow
- Maintaining turf health without creating unduly lush growth, especially in autumn
- Maintaining an appropriate soil pH (generally in the region of 5.5 – 6.5)
- Monitoring and a keen awareness of the weather conditions that are favorable to the development of disease
- Making use of disease prediction resources such as the green- cast.co.uk website
- Working towards the establishment of grass types with improved disease tolerance
- Using fungicides properly and at an early stage

Fungicide use and spraying
Even with the best cultural practices in place, disease outbreaks can occur if the environment is favourable enough for long enough. Fungicide use should be considered as part of an integrated turf management plan rather than a firefighting approach. Using fungicide to control the inoculum, halt the development of the pathogen and protect the plant is good practice, especially if there is a significant risk of damage.

You will know that there are a number of fungicides available and that they can have different active ingredients. In general terms, active ingredients are designed to either target the fungi with direct contact (to interrupt its development) or be situated within the plant itself to repel infection by the pathogen from within. Different active ingredients work in different ways, so it is important to select products that are appropriate for each situation. It is best practice to alternate treatments with different modes of action or use products with multiple active ingredients to prevent fungicide resistance occurring in the fungal population.

Which active?
By way of example, fluazinam belongs to the phenylpyrrole chemistry group. It is targeted for direct contact with the pathogen and has multi-site activity inhibiting the germination of spores, the creation of hyphae and mycelial growth. It acts in the soil, in the thatch and on the leaf and is an effective preventative, as well as an early curative treatment.

Fludioxonil is a member of the DMI-fungicides group, and has rapid systemic uptake through the leaf and crown of the plant. It acts on the pathogen from inside the plant, to stop disease development after penetration by interfering with sterol biosynthesis in fungal cell membranes. It is best applied preventativey and is shown to be particularly effective in cooler conditions.

Amitrole is a strobilurin of the QoI group. It is systemic; enter- ing the plant through the roots, crown and leaf, and prevents fungal growth by affecting its cells. This can be applied at any stage but is best applied preventativey.

Some fungicides contain a mix of active ingredients to achieve better control by targeting the pathogen at different growth stages, or in the thatch and soil as well as inside the plant.

Conclusion
Microdochium patch can be an especially damaging disease if given a free rein to grow and reproduce. It is important that we work hard to minimise the risk of attack with good management practice. Fungicide treatment is often necessary, and an appreciation of the disease life cycle and fungicides’ mode of action will help achieve the best results.

However, the pathogen will never be completely eradicated, so we must remain vigilant and properly prepared. Our essential weapon against Microdochium patch is undoubtedly our knowledge and understanding, which we can use to create an advantage at least. Sometimes, it’s better to know the devil.

The (not so) elusive butterfly bush

In this latest series of BASIS articles written in association with Sherriff Amenity, Graham Paul looks at the butterfly bush

The Butterfly Bush, Buddleia davidii, was introduced to the UK from China in 1896. It is loved by many gardeners throughout the world for the abundance of beautiful, scented and nectar-rich flowers that attract butterflies, bees and other insects.

It is easy to propagate and has few natural enemies, so once it is established in a garden it will probably remain there in perpetuity. I have chosen to feature this plant because it is a non-native invasive species that can be difficult to control; and also to highlight the controversy that arises from the impact it has on local ecosystems.

The genus Buddleia comprises over 100 species that originate in Asia, Africa and the Americas. The genus was named by the Swedish botanist Carl Linnaeus as a posthumous honour to the Reverend Adam Buddle (1662–1715), a rector and botanist from North Fambridge in Essex, who was the foremost authority on British bryophytes of his era - just imagine what his Sunday sermons were like!

The most common of the buddleias is B. davidii, which gets its species name from a French missionary and naturalist Pierre Armand David. Buddleias are now classified in the Scrophulariaceae family, a large group of plants that includes fritillaries, mulleins, toadflaxs and speedwells. Prior to this they were classified in their own family, the Buddlejaceae.

The Butterfly Bush grows to a height of up to five metres. Flowers are borne in dense, spiked panicles that are mauve-purple with an orange centre. A white flowering variety can also be seen growing in the wild but is less common than the purple flowered species. Originally introduced as a garden bush it has escaped and can be extremely invasive given the right conditions.

The potential for spread of this species is due to the large number of seeds produced by each of the tightly packed flower spikes. It is estimated that a single flower spike can produce as many as 40,000 seeds so a full sized bush could generate as many as 3 million in a year. These lightweight, winged seeds are easily dispersed by the wind and are often caught in the slipstream of lorries and railway trains that can carry them onwards for a considerable distance.

The seeds can remain viable in the soil for three to five years, requiring very little in the way of soil or moisture to germinate and hence they can easily establish in barren ground.

The butterfly bush occurs in a variety of habitats, growing well on poor soils with a preference for disturbed ground and areas recently damaged by fire. It seems to like chalky and lime soils, waste ground and will also proliferate on riverbanks.

Another favourite habitat is railway property; where it easily establishes in the ballast of the track and can be pulled up relatively easily and established mature plants can be pulled up relatively easily and cut as they can take root and create dispersal.

High on the list of new products specifically suitable for controlling the butterfly bush in amenity situations are mixtures of amipyrnid and triclopyr, developed by Dow AgroSciences and launched under the brand names ‘Timbrel’ and ‘Speedline’.

The initial approach to curb the spread of this plant using non-chemical means is to control the spread of seeds. Dead-heading plants as soon as the flowers have died back is recommended for garden specimens but on larger bushes this may not be practical. Landscapers and gardeners should be encouraged to choose new dwarf varieties of Buddleia that do not produce fertile seeds; such as ‘Blue Chip’, which is equally attractive to butterflies but does not present any risk of spread by wind dispersal.

Seedlings and young plants can be pulled up relatively easily and established mature plants can be killed and disposed of by burning on site if this is permitted. It is inadvisable to leave any branches on the ground after they have been cut as they can take root and create a new plant.

Biological Control measures

Authorities in New Zealand have carried out quarantined studies on the leaf eating weevil Cleopha japonica to ensure it did not harm endemic plants and crops. This insect originates in China where it...
