How to Control Turf Diseases

In recent years the turf business has received increased emphasis because more homeowners are trying to match the lawns and landscapes found on golf courses, large estates, and around well-kept industrial sites. The care and special treatment required for the upkeep of these lawns, however, is far beyond the usual homeowner's ability. Contract applicators, consequently, may be called in to treat ailments.

CAs may also have a problem if the lawn deficiency is unfamiliar to them. One big headache is the control of fungus diseases on turf. Avoided in many cases because of the complexity of the pest organisms, fungus control is a service which, when mastered, provides the CA increased business potential, and helps make his services complete.

Many homeowners don't realize how common fungus-caused turf diseases are. Incidence of fungus damage is often passed off as "bad grass" or "dog spots" (caused by the urine of female dogs), which will return to life in due time. Unfortunately, this diagnosis is not always true, and a lawn may be severely afflicted by a fungus disease before the cause is identified.

Fungus Infection

Turf grasses, like human beings, have resistance levels. As long as grasses are well kept, there is less chance of infection. But if care is slipshod, chances for fungus damage are greatly increased.

Fungi, assumed by many to live only on dead or decaying matter, have been observed to attack live grasses which are in a weakened condition. Infection of this sort further reduces resistance and paves the way for multiple outbreaks, which lawn experts refer to...
as a "tandem" infestation. When two or three fungi infest a lawn at the same time, diseases are harder to identify, and much harder to control.

Disease-inducing fungi are generally always present in or on the sod, in degrees below infestation levels, in the mat and thatch (dead, decaying materials or litter, such as roots, stems, or leaves). When the mat and thatch become too abundant, as they do when grass clippings are not removed, the fungi may begin to grow rapidly. Other conditions which affect the development of the fungi are: temperature, humidity, injury to the turf through excessive wear, and improper cutting, which lower the resistance. When such conditions exist, healthy turf may be transformed into bleached, barren patches.

Parasitic fungi are referred to as diseases because they kill or severely injure the grasses.

Infestations may result from one of three classes of fungi. Of the Class Basidiomycetes, which includes the bracket fungi, smuts, rusts, and toadstools, only the last two are prominent as turf pests. The Class Ascomycetes, or sac fungi, includes parasitic mildews and pathogenic scabs and blights. Class Phycomycetes includes the water molds of which the Pythium blight is a good representative.

Identification of a single diseased area can sometimes be made simply by observing the results of fungal activity on the grass; perhaps a correlation can be made with a universally common descriptive name, such as "dollar spot." A good, close look should be taken by placing a plug, taken from the edge of a suspected area, in a dish overnight with a piece of moistened paper towel. If there is an infestation present, a "cobwebby" growth of mycelium or fungus threads should be seen on the blades of grass the following morning. Sample plugs can be kept fresh by moistening them in a wrapper of aluminum foil, or a polyethylene bag.

**Microscope Helps Identify Fungi**

If no identification can be made with the naked eye, a few blades of dying grass should be placed on a slide for microscopic examination. Using a key to turf fungi available from some of the chemical manufacturers, or a textbook, the exact species of the infestation can be ascertained.

Sometimes the most obvious signs of infestation are not observable until the last stages of infection. In this case, all effort should be made to determine the fungus species, and the control methods, before too much damage is done.

A novice in the field of fungus control should have his diagnosis checked by either a government agency specialist or a local turf management expert.

Records of outbreaks should be kept by those in fungus control. This record should include: the species of fungus, grasses affected, specific location, date of occurrence, and environmental conditions a week prior to the outbreak (weather, extent of lawn use, management practices such as fertilization, etc.). Control practices and results of treatments should also be included for future reference. This will eventually lead the CA to a planned program of lawn fungus prevention and correction.

**Chemicals and Application**

A number of fungicides are available for turf disease control. This article includes the common names of a few of the active ingredients now marketed. These active chemicals may be obtained in "single component" form or formulated with other ingredients to produce a "broad spectrum" preparation. The latter, gaining in popularity, is used for controlling and preventing a number of fungus diseases with one application, although applications often must be made several times a month when heavy infestations are expected.

Cadmium-based compounds, such as cadmium carbonate, cadmium sebacate, and cadmium chloride are effective against "dollar spot." Mercury-based compounds, such as calomel (mercurous chloride) and corrosive sublimate (mercuric chloride), help combat infestations of brown patch.

Some others which are used in fungus control are: cycloheximide, dyrene, thiram, zineb, methyl mercury diecyandiamide, and phenyl mercury acetate. Fumigation with formaldehyde or methyl bromide is sometimes practiced for eradicating fairy rings.

The most popular preparations are the water soluble or wettable powder forms. When properly agitated these types can be applied with any sprayer.

Application to the soil by syringe injection is sometimes called for in cases of fairy rings, for example, when the turfgrass may be injured by surface applica-
tion of a chemical such as phenyl mercury acetate on Kentucky bluegrass.

Increasing in popularity is the granular form, which requires less time for preparation, less bulky equipment, and requires less handling.

Choice of application method will depend upon the formulation, the area to be treated, and available equipment.

In order to help the contract applicator better cope with fungus disease problems, here are some of the more common turf diseases, descriptions, and control methods for them.

**Anthracnose**

Anthracnose, caused by an imperfect fungus (species without sexual reproduction) of the genus Colletotrichum, can be a serious problem with cultivated grasses and is often found in conjunction with a condition known as melting-out. Anthracnose is recognized by irregularly outlined patches of blighted turfgrass. The infected areas range from 2 inches to 10 to 20 feet in diameter. From a distance, CAs can see reddish-brown patches which are caused by lesions or wounds on the leaf blades. Blades of grass may have a cobwebby growth of the fungus on them in the early morning. Progression of the disease causes a light-tan coloration throughout the infected area. When infected leaves begin drying out, they appear on close examination to have black spots as a result of the spiny black fruiting (spore-bearing) bodies which will reproduce the disease. Anthracnose is common throughout the United States, attacking mainly fescues, bents, bluegrasses, and ryegrasses. The disease survives below infestation levels in organic debris on the soil surface.

Successful chemical control of this pest has not been developed. Cultural practices, such as high, balanced fertilization, and irrigation at field capacity may reduce the problem.

**Brown Patch**

Brown patch, caused by an imperfect fungus, *Rhizoctonia solani*, is characterized by irregular circles up to 2 feet in diameter, in areas where mowing has been close. The circles have an over-all purplish color, later turning to light brown as the diseased leaves dry out. When mowing has been high, blighted areas may extend up to 50 feet in diameter.

Brown patch becomes evident mostly during warm, humid weather. Diseased areas are best recognized when the grass has dried out about midday, especially after mowing. The "smoke ring" effect of brown patch gives the infected area a sunken appearance. This effect is seen in the morning when there is dew on the grass.

Temperature plays a large part in the development of this fungus. From 64° to 69° F, the fungus grows below infestation levels. At 73° F it will spread, penetrate, and infect the grass leaves. Infestations flourish at temperatures around 80° to 85° F. Brown patch may completely blight a considerable stand of turf in 6 to 8 hours at temperatures in this range.

Grasses susceptible to brown patch include bents, bluegrasses, and Bermudagrass.

For control, cultural and chemical practices go hand in hand. Fertility of the soil affects the development of the fungus. When the soil is balanced with fertilizer, the disease effects are not great. If the pH (acidity or alkalinity) is high or in the alkaline range, and there is excess nitrogen present, the disease usually gets the upper hand. If the soil is acidic, i.e. the pH is below 7, which is neutral, low nitrogen fertility fosters fungus development. Also conducive to development is excess water during periods of high humidity. Over-watering and over-feeding of grass should be avoided during the hot, humid summer months.

Fungicide applications should be made weekly when the weather is right for brown patch development. Mercury-based fungicides, such as calomel and corrosive sublimate in a 1:1 mixture, applied at the manufacturer's recommended rate, are the most popular. Since the compounds can injure grasses if not used properly, label directions must be followed exactly.

**Dollar Spot**

Dollar spot is a widespread fungus disease of short-cut bentgrass caused by *Sclerotinia homoeocarpa*, an imperfect fungus. It is so named because the infected area is usually not larger than a silver dollar. Individual leaves appear blotched with yellow green, later bleaching to a straw tan. A fine cobwebby growth or white fluffy mass can be seen on each of the "dollars" on mornings when dew is present. The cool nights and warm days, (70° to 80°) which form dew, also foster dollar spot development. If this disease is left to run its course, the spots may merge and produce large damaged areas. Spread of the disease is in a circular manner from the center of infection, but it may also be spread by moving sprinklers over the disease area and from transporting and spilling infected clippings over the lawn.

Dollar spot thrives during periods of low moisture, and if not controlled, may ruin a stand of turfgrass. The grass will recover quickly, however, if a good con-
control program is followed early. Fungicides containing cadmium, such as cadmium chloride or cadmium oxyquinolinate, when used in conjunction with a good management program which includes fertilizing with nitrogen and irrigating to a point below runoff, should give ready control of dollar spot. Some others which were successful in trials are: methyl mercury compounds, thiram-based compounds, and captan-based compounds.

**Copper Spot**

Copper spot appears identical to dollar spot except that the infested areas are a true copper color. Copper spot is also similar in that it thrives in warm (65° to 75°), humid periods. Attacking mainly bentgrass, copper spot, 

*Gloeocercospora sorghi*, is a pest throughout the United States, but is most damaging in coastal areas. Control measures are the same as those recommended for dollar spot, except that grass infested with copper spot should not be watered as much as when dollar spot is present.

**Cottony Blight**

Cottony blight, known also as grease spot, fire streak, and damping-off, is caused by water molds of the genus *Pythium*. These fungi are very destructive, and once conditions are right for their development, are capable of destroying stands of lawn grasses within 24 hours. Complete remaking of the lawn is often necessary after an outbreak.

Cottony blight, and other fungi of the genus *Pythium*, develop mainly in poorly drained areas, and may attack any species of grass. The common names are descriptive of its appearance. At the onset of infection, it appears as small (up to 4 inches diameter) irregular spots. The leaves turn dark as if water-soaked. Later they shrivel, become matted, and have a “greasy” light-brown color. Since low water runoff areas are unfavorable for development, it is common to see the fungus streaking by the spreading of the pathogen in running water. This fungus also appears as white “cobwebs” on dewy mornings.

A dithiocarbamate, such as zineb, is effective, along with a good management program, in eliminating this hard-to-control disease. Cultural practices include: providing good drainage; maintaining balanced fertilization; and keeping the soil within the acid pH range (below 7) by giving it sufficient water (if the pH is over 7) to leach out the alkaline components. Overwatering, however, will result in the same conditions that the program is trying to eliminate. Accompanying fungicide applications of zineb at the rate of 2 oz. of 50% wettable powder in 5 gallons of water per 1000 sq. feet should be made at 5 to 7 day intervals when the temperature is in the 80° to 95° range. If the temperature goes above 95°, applications should be made every 3 to 4 days for effective control.

**Fairy Rings**

Fairy rings are common in soils with excess decaying matter. Caused by a number of different fungi of the “toadstool” type, the common name is descriptive of the growth pattern of these organisms. Radial growth is caused by the yearly extension of the underground mycelium or “root” system. Each year during damp periods the mycelium send up fruiting bodies or “toadstools.” Although the circle of “mushrooms” attracts curious attention to the phenomenon of the fairy ring, the fungal mycelium can nevertheless damage turf severely by cutting off water from the grass roots. The pattern of infestation is usually as follows: first, an inner area of grass is encircled by a stimulated zone (caused by excess nitrogen produced by bacteria in the old growth zone of the mycelium); this is followed by a circular strip of dead grass, all within the ring of toadstools. Another zone of stimulation appears just outside the ring.

Control and eradication of fairy rings is accomplished either by drenching, or removal of infested sod and fumigation. Drenching technique, which suppresses growth, involves removing small plugs, 2 to 4 inches deep and 6 to 8 inches apart, around the outside and throughout the affected area and inserting a fungicide by means of a battery-type syringe. Either phenyl mercury acetate or a cadmium compound, at twice the recommended amount for foliar application, squirted into the plug holes, should do the job. The plugs should be replaced and the area drenched with not less than 1 inch of water. (Phenyl mercury acetate should never be used on Merion Kentucky bluegrass.)

Fumigation with methyl bromide follows standard fumigation techniques with modifications. After removing all of the infested sod, taking care not to spill any on healthy turf, the area should be covered with a fumigating canvas.
or plastic cover. Evaporating pans should be placed at regular intervals and be accessible from outside the cover. Odorized methyl bromide is then inserted under the cover into the pans at 2 lbs. per 100 sq. ft. After 36 to 48 hours, the soil should be allowed to aerate for 7 to 14 days before remaking.

Fumigation with formaldehyde is less dangerous but requires more time under cover and a longer period to aerate. Either type of fumigation is hazardous and should not be attempted by anyone who has not had previous experience with the chemicals and the techniques involved in their use.

**Snow Molds**

Snow molds are caused by any of several fungi which thrive in cool, wet, humid conditions like those found in the snow belt of the United States in late winter or early spring.

Gray snow mold, also called snow scald and winter scorch, is caused by a small basidiomycete called *Typhula iooana*. First noticed after spring thaw as light yellow areas about 1 to 2 inches in diameter, the infection centers soon enlarge and turn grayish white due to the strands or growing fungus and the decomposition of the grass leaves. Small fungus bodies (sclerotia), no larger than 1/16 inch diameter, can be found embedded in the infected blades of grass. The sclerotia appear yellow or light brown in the early stages, turning dark brown as they mature.

Pink snow mold, caused by *Fusarium nivale*, is also recognized as a yellowish, irregular cirlce, although it's actually an ascomycete.

Under snow cover on unfrozen ground, the white mycelia develop over the grass blades. With the melting of the snow, the mycelium turns pink upon exposure to the sun. This fungus usually attacks only leaves, but occasionally will damage crowns and roots of grasses, making complete reseeding necessary.

**Red Thread**

Red thread, *Corticum fuciforme*, is a basidiomycete which does great damage to almost all of the cultivated grasses in the cooler, more humid portions of North America and Europe. It first appears as irregular blighted patches up to 3 feet in diameter. On close observation the fungus is seen to be a small dark green spot on the grass leaf. The leaves begin drying out, as the disease advances, and turn tan. In the final stages, the dead leaves have fine threadlike filaments of fungus at their dried-up tips which are a characteristic coral-pink color.

Fungicides containing mercury or cadmium compounds applied along with fertilizer to speed up growth and aid recovery should combat red thread.

**Rust**

*Puccinia graminis*, better known as rust (one of several species), appears 10 days after infection as light yellow flecks or lesions on the leaf blades. These lesions gradual-

(Continued on page W-11)
An excellent text on the subject, Diseases of Turfgrasses by Houston B. Couch (See book review, August, 1962), would be helpful to anyone interested in this new, exacting, and expanding phase of a contract applicator's service.

Editor's Note . . .

This original article on turfgrass diseases was prepared by Weed's and Turf's technical staff, from available literature and our own investigations. While opinions presented are strictly our own, we wish to thank the companies which reviewed our manuscript and made helpful suggestions. Firms especially cooperative were Chemagro Corp., The Dow Chemical Co., E. I. DuPont de Nemours and Co., Morton Chemical Co., The Mallinckrodt Chemical Works, and the Upjohn Co. We also thank university researchers who reviewed the text.

Additional information concerning the identification and control of fungus diseases affecting turfgrass may be obtained in booklets produced by extension services, or by fungicide manufacturers.

Turf Diseases
(from page W-6)

ly enlarge and elongate parallel to the veins in the leaf. Reddish-brown (rusty) pustules are exposed as the outer layers of grass tissue are ruptured. The disease eventually turns an entire stand of grass yellow. The bentgrasses are relatively immune to rust infection, whereas Merion bluegrass is very susceptible.

With the rising popularity of Merion Blue the rusts are now considered to be among the more important and costly turfgrass diseases. Outbreaks may be expected in July or August.

Cycloheximide can be effective against rust if applied at the rate of 2 gallons of 60 ppm per 1000 sq. ft. Zineb applied at the rate of 2 oz. per 1000 sq. ft. in 3 to 5 gallons of water will also combat rust. Most of the fungicides are aided in their action if a commercial spreader-sticker is used with the preparation.

Preventative practices include nitrogen fertilization and application of granular urea.
